Abstract— In this paper, we propose a new multichannel allocation protocol for ZigBee/IEEE 802.15.4 networks. The main goal is to improve the global throughput which is basically insufficient to satisfy high bandwidth requirements for applications like monitoring or traffic control. The solution is based on the availability of multiple channels on current low-cost, low-energy radio transceivers, such as CC2420, which can be easily tuned dynamically to different frequencies. This possibility can be exploited to increase the number of simultaneous transmissions on adjacent links. The allocation of the different channels is centralized and distributed by the coordinator thanks to a function designed to compute the channel offset between two successive children routers. In the nodes, the switching process between the transmission and the reception channels is triggered starting from the PHY primitive available on the transceiver. The evaluation shows that the proposed protocol improves the global throughput by a factor between 2 and 5, depending on the scenario, compared to the single-channel solution or a random channel allocation.

Keywords: *Multichannel, Wireless Sensor Networks, IEEE 802.15.4*

I. INTRODUCTION

The bandwidth available in Wireless Sensor Networks (WSN) is generally insufficient to satisfy greedy applications such as low/medium resolution video monitoring. For instance, the theoretical throughput in prevalent WSN standards such as ZigBee or 6LowPan is upper-bounded to 250kbps. As wireless sensor networking evolves toward multimedia sensing, it becomes necessary to find new mechanisms to transmit more efficiently audio or video flows.

This study considers realistic application scenarios with high bandwidth requirements and takes into account the characteristics of existing sensing technologies. These scenarios are typically part of the paradigm that is Multimedia Sensor Networking [5] wherein sensing devices are more powerful and embedded with CMOS cameras and audio sensors. In such networks, nodes are deployed in a specific area in order to provide various services like traffic congestion control, video monitoring, object tracking and recognition, etc. In this work, we consider an IEEE 802.15.4 wireless sensor network with a hierarchical topology: coordinator, router and terminal divided in several levels of clusters. The transmissions use the 802.15.4 non-beaconed mode which allows the best bandwidth utilization [15].

In addition, we are interested here only on single interface solutions. Multiple interface schemes are not adapted to ZigBee devices because of their energy consumption limitations. In WSNs standards, much smaller packet sizes are used (e.g. ~100 bytes for IEEE 802.15.4) compared to those in wireless ad hoc networks (e.g. 1500 bytes in IEEE 802.11). The solutions with control packets like RTS/CTS in IEEE 802.11 will not be adopted as they can lead to an important overhead.

Current low-cost, low-energy radio transceivers, such as CC2420 [3] can be tuned dynamically to different frequencies allowing PHY protocols to operate on different radio channels. The availability of multiple channels on the wireless medium can be exploited to increase the number of simultaneous transmissions between different pairs of transmitter/receiver. Thus, the global network throughput can potentially be increased. However, no channel switching protocol is proposed in IEEE 802.15.4 standard. That is why, in this paper, we propose a new protocol for the channels assignment named MASN (Multichannel Access for Sensor Networks), based on an offset function comparable to the one used in the hierarchical ZigBee addressing. Channels on the different links are successively allocated by the coordinator after the association process, starting from the first children routers and toward the end terminals. The proposed protocol ensures that two neighboring links will not be affected by the same channel. In addition, the protocol introduces a switching process between transmission and reception channels. This process is triggered starting from the PHY primitive available into the transceiver.

Insofar as the protocol does not modify the medium access method but only adds channel allocation and channel switching process in the nodes, it can be easily implemented in IEEE 802.15.4 device. The MASN protocol is thus designed in accordance with the 802.15.4/ZigBee networks standard which is not the case of many proposed solutions in literature.

The rest of the paper is divided into five sections. In section 2, we sum up the existing works dealing with multichannel access in wireless networks. We present our MASN protocol in section 3. Section 4 is dedicated to the performance evaluation of the proposed protocol. The fifth section concludes our paper and presents the future works.

II. RELATED WORKS

In many studies designed for general wireless networks [6,7,8], transmission are divided into two period: a control period with a common channel to exchange information between all nodes about free channels or to schedule channels available for future data exchanges (this period is often called ATIM window for Ad Hoc Traffic Indication Messages window); a period for simultaneous data transmissions between several pair of sender/receiver in a channel selected during the control period. These protocols are not adapted to an 802.15.4 context as all nodes' interfaces have to listen to the common channel during frequent and periodic negotiations which can be very greedy in terms of energy consumption.

The SSCH protocol [9] proposes a different approach where each node computes a channel schedule which contains the list of channels that a node plans to switch to in subsequent slots (the time spent on a single channel). To ensure that communications with neighbors are possible in some slots, each node has to maintain a list of the channel schedules for all other nodes it is aware of. The principal drawbacks of this approach in our WSN context is the high control traffic used by all nodes to periodically broadcast the channel schedule and the necessity of synchronization between nodes.

In order to consider more specifically the WSNs constraints, other works are proposed. As for MMAC [7], the TFMAC protocol [10] divides time into a fixed number of slots and allows each node to use different frequencies within different time slots to send data packets to its neighbors. The authors propose to create a TDMA frame with contention period and contention-free period which already exist in the 802.15.4 standard with the superframe in the beacons mode. No indication is given on how to synchronize the TDMA frame between the nodes (in IEEE 802.15.4, the coordinator synchronizes the superframe on a common channel).

The MMSN protocol presented in [11] is also especially designed for WSNs and consists of two aspects: frequency assignment and media access with a specific design, different from the classical CSMA. The global throughput is significantly improved with MMSN, but the comparisons are carried out with a theoretical CSMA MAC layer and not with a real MAC IEEE 802.15.4 layer. Moreover, selected topologies are not hierarchical and the traffic pattern is many-to-many and not many-to-one like in usual WSNs or more specifically in MWSNs.

Soroush et al. proposed a hybrid TDMA/FDMA MAC protocol called HYMAC [12] in which data gathered by sensor nodes are delivered to a base station (many-to-one traffic). The transmissions take place in a fixed-length TDMA cycle divided into several fixed time slots. The base station assigns an appropriate frequency (FDMA) and a specific time slot(s) to each node (TDMA) by running a scheduling algorithm. The simulation results show that HYMAC outperforms MMSN for the number of potential conflicts but these performances are obtained by adding time slots when the number of frequency is insufficient which increases the risk of interferences. Consequently, the MAC layer is specific and not directly compatible with the IEEE 802.15.4 MAC layer or another CSMA/CA MAC layer.

In [13], Wu et al. propose TMCP, a tree-based multi-channel protocol. The main idea is to assign channels to different subtrees instead of nodes in order to avoid interference between nodes of different subtrees (inter-tree) without the need for time synchronization. A comparison shows that the performances of TMCP and MMSN [11] are very close. The main drawback of TMCP protocol, according to our selected context, is the lack of coordination between the tree-based channel assignment scheme and the hierarchical association process already existing in ZigBee networks.

MCMAC [14] is another protocol designed for multichannel access where the sensor network is divided into clusters like in a hierarchical ZigBee network. The proposed protocol increases the network energy efficiency and the data throughput thanks to a time slotted access in a synchronous beacons mode. Even if the average throughput is better than that obtained with a mono-channel access, the performances of the beacons mode remain globally insufficient [15] for multimedia flows.

III. MASN PROTOCOL

A. Context and goals

As mentioned above, this study takes into consideration the technical characteristics of existing WSNs and relates to sensor networks with high bandwidth demand in which data are destined to a unique sink. Such context imposes some assumptions for the network and its components:

- static nodes limited to 50 and distributed on a surface lower than 100x100m (current deployments of ZigBee networks in home automation or monitoring contexts are generally composed of less than 50 nodes) ;
- hierarchical clustered topology with a single sink;
- ZigBee/IEEE 802.15.4 technology for routing, MAC and PHY layers;
- hierarchical ZigBee routing for many-to-one transmissions (different from a reactive ad hoc routing for many-to-many communications which is the case of many studies on the subject [6-11]);
- a single radio interface by node (except for the ZigBee coordinator which serves as sink);
- the IEEE 802.15.4 technology proposes a total of 16 non-overlapping channels the 2,4GHz band; one control channel is dedicated to the association process (channel 11) and 15 channels are used for the data transmissions (channel 12 to 26);
- the change of channel respects the switching time of the radio transceiver (typically 200µs for the CC2420);
- the CSMA/CA access method in the non-beacons mode is chosen as it provides the best throughput [15].

Furthermore, we chose neither to use a temporal window on a common control channel to negotiate periodically a data channel between receivers and transmitters [6-8] nor control MAC frames (RTS/CTS), as these solutions consume time and energy (cf. section II).

Finally, the proposed protocol must be able to be easily integrated on usual sensors equipped with a CC2420 transceiver (for example TelosB, MicaZ and Imote2 provided by MEMSIC, formerly Crossbow, [4]) without important modification of the MAC layer: the medium access method is not modified (case of the algorithms with a control window).

B. MASN Overview

1) Channel allocation

The algorithm proposed for the channel allocation is inspired by the hierarchical address allocation process used in the ZigBee networks. In this process, the *Cskip* function is used to compute the address offset between two successive children routers for a given network depth, d :

$$Cskip(d) = \begin{cases} 1 + Cm \cdot (Lm - d - 1), & \text{if } Rm = 1 \\ \frac{1 + Cm - Rm - Cm \cdot Rm^{Lm-d-1}}{1 - Rm}, & \text{otherwise} \end{cases}$$

Lm being the maximum depth in the network, Cm the maximum number of children a parent may have and Rm the maximum number of routers a parent may have as children.

Then, network addresses are assigned to end-devices in a sequential manner with the n^{th} address, A_n given by the following equation:

$$A_n = A_{parent} + Cskip(d) \cdot Rm + n$$

Where $1 \leq n \leq (Cm - Rm)$ and A_{parent} represents the address of the parent.

In ZigBee specifications [1], three roles are possible for a node: ZC is the Coordinator, ZR is a Router (these two roles corresponding to an 802.15.4 MAC Full Function Device) and ZED is an End Device (Reduced Function Device).

In our algorithm, like in HYMAC [12], the coordinator distributes the channels after the node-association process. The channel allocation is related to the ZigBee network parameters Lm , Cm , Rm . Insofar as the values of these three parameters characterize the size of the network, the frequencies allocation is also directly limited by these values.

Each node uses one channel to send data (CHS) towards its single parent. In our solution, the number of reception channels (CHR) for a ZR is also limited to one. This limitation avoids a commutation algorithm between several CHR based on TDMA multiplexing or on advertising frames sent on the common channel. Indeed, these two solutions would involve additional delays and would be difficult to integrate in a standard device. Moreover, the first solution (TDMA) would be contrary to the initial choice which is to use a CSMA mode in order to optimize the global throughput. The number of possible channels (n_{CHS} and n_{CHR}) for the different roles is summarized in the example depicted in figure 1.

Figure 1. Example of Channel Allocation

A function comparable to $Cskip(d)$, named $CHSkip(d)$ is used to compute the channel offset between two successive children ZR. Insofar as the allocation of the CHR is necessary only for the ZR (as indicated previously, the ZC can have several radio interfaces with one channel per interface), $CHSkip(d)$ depends on Rm and not on Cm . For a given value of Lm and Rm , for example $Lm=4$ and $Rm=2$ as in figure 1, $CHSkip(d)$ can be computed as follows:

$$CHSkip(2) = 1 + Rm = 3$$

$$CHSkip(1) = CHSkip(0) = 1 + 1 + (1 + Rm)Rm = 8$$

Finally, we can generalize the $CHSkip(d)$ expression:

$$CHSkip(d) = \begin{cases} 1 + \sum_{n=0}^{Lm-d-1} Rm^n, & \text{if } d \leq 1 \\ \sum_{n=0}^{Lm-d-1} Rm^n, & \text{otherwise} \end{cases}$$

Then, the CHR values are assigned to the ZR in a sequential manner with the n^{th} channel, CHR_n , given by the following equation:

$$CHR_n = \begin{cases} [12 + CHSkip(d) \cdot (n - 1)] \bmod 15, & \text{if } d = 0 \\ [CHR_{parent} + 1] \bmod 15, & \text{if } d = 1 \\ [CHR_{parent} + 1 + CHSkip(d) \cdot (n - 1)] \bmod 15, & \text{otherwise} \end{cases}$$

This allocation is illustrated in figure 1 with the different values of $CHSkip(d)$ at different depths and with the successive allocated channels. Let us note that the solution combines a channel assignment not only to different subtrees, like in TMCP [13], but also to the different hops in the same subtree. It is demonstrated in [17] that a multihop multichannel allocation scheme is efficient in an 802.15.4 network.

With these equations, the channel distribution does not directly guarantee, like in MMSN [11], that two neighboring links will have a different CHR (the offset can be equal to 15 which is the number of possible channels) but the probability is weak with 15 channels and a hierarchical distribution (2 routers associated to the same parent will always have two distinct channels). However, to avoid this case, the algorithm attributes $CHR = n+1$ instead of $CHR = n$ for a ZR having a neighboring router of the same parent and with $CHR = n$.

In addition, as for the hierarchical addressing process, the centralized channels allocation can be reorganized if the

network is modified because of the transition to idle state, the stop or the displacement of a node.

Finally, the algorithm validated on a ZigBee network with one ZC can be extended to the other ZigBee networks considered then as clusters with ZC acting as Cluster Head which distributes channels on the links.

2) Channel switching

CHR is selected by default on a ZR. On reception of a PHY primitive PD_DATA_REQUEST() indicating a data frame transmission request, ZR switches to CHS (if it is not receiving). The change of channel is effective after the device switching time (figure 2). ZR returns to CHR when the MAC acknowledgment is received, after another switching time. A timeout is triggered for all the data transmissions, at expiration of this timeout and in the absence of a MAC acknowledgment, the node automatically returns to CHR.

As in any ZigBee network, it is necessary to be able to re-associate a node which becomes orphan because of a link failure due to the extinction of the parent node or to interferences in the vicinity. The control channel is thus periodically switched following a command sent by the coordinator to all the nodes.

Figure 2. Channel switching Timing

IV. PERFORMANCE EVALUATION

A. Simulation scenario

The parameters used in NS2 simulator [16] are adapted from those of the CC2420 transceiver, in particular for the channel switching time (200µs). They are summarized in table 1. The selected scenario is described in figure 3, it corresponds to a hierarchical clustered topology with a maximum depth of 4 hops ($Lm=4$) and a maximum of 3 children by router including 2 children routers ($Cm=3$ and $Rm=2$). The distances between nodes are chosen so that each node has 1 or 2 hops neighbors. The CBR sources are distributed in the ZED of the different clusters with a maximum of 25 sources and a maximum CBR frequency of 30 packets/s; these values are selected to reach the saturation of the network.

Four solutions are compared: mono-channel; our MASN protocol; a random allocation of the 15 data channels (named Random) and an allocation of a different channel for each subtree of the network (named Subtree) comparable with the one used in TMCP [13] but without the tree building process which is carried out in our solution by the ZigBee protocol. For

the two last solutions, as for MASN, only one reception channel is allocated for each child router.

TABLE 1: SIMULATION PARAMETERS

Physical Channel	802.15.4 - 2.4GHz
Data Rate	250 kbps
Reception range (Capture Threshold)	15m
Detection range (Carrier Sense Threshold)	30m
Maximum surface	100x100m
Number of nodes	46
Propagation Model	TwoRayGround
CBR packet size	97Bytes
Routing Protocol	ZBR
Simulation Time	60s

Figure 3. Simulated Network

B. Simulation Results

Figure 4 shows the evolution of the network global throughput according to the CBR sources frequency, when almost 50% of the sources (12/25) are activated. For the mono-channel solution, the throughput is always lower than 60kbps and decreases for frequencies greater than 8 packets per second. The numerous contentions on the data common channel induce important latencies related to the CSMA/CA algorithm. The global throughput obtained with MASN protocol increases linearly to reach a value close to 190kbps at a frequency of 30pkts/s, this threshold is not the maximum but beyond, the delivered packets ratio becomes lower than 50%. This ratio is represented in figure 5 for the four solutions. The saturation in the mono-channel is confirmed by this measurement: delivered packets ratio is lower than 80% for frequencies greater than 8pkts/s. This ratio remains higher than 90% up to a frequency of 10pkts/s in the multichannel solution, which shows the weak number of contentions and thus the efficiency of the solution.

The random allocation gives intermediate performances insofar as it does not avoid identical channels on adjacent or neighboring links, which can involve conflicts. For the Subtree

solution, the performances are close to those obtained with MASN for weak traffics (CBR frequencies lower than 15pkt/s). For higher traffics, the throughput and the delivered packets ratio decrease because of the numerous conflicts on the subtrees sharing the same channel.

Figure 4. Global Throughput/CBR Sources Frequency

Figure 5. Packet Delivery Ratio/CBR Sources Frequency

Figures 6 and 7 show the same metrics as the number of CBR sources increases. The sources are gradually activated on the different subtrees (one source per subtree, then two sources per subtree ...) to delay the contentions, particularly in the mono-channel solution. In this case, the difference in performance between the solutions is less important, in particular for the Subtree solution (the progressive activation of the CBR sources favors this solution) but MASN protocol gives a much higher throughput for a delivered packets ratio close to 90%.

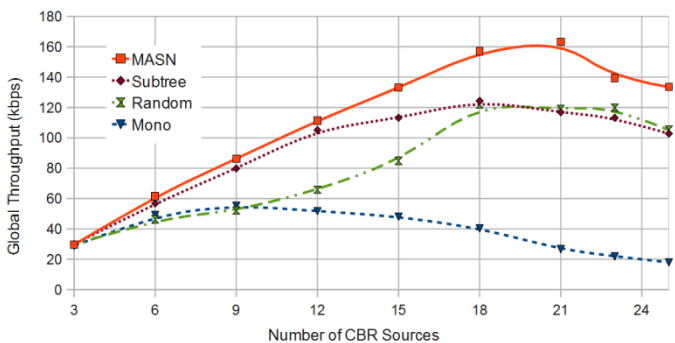

Figure 6. Global Throughput/Number of CBR Sources

Figure 7. Packet Delivery Ratio/Number of CBR Sources

V. CONCLUSION

We have studied and tested a multichannel allocation solution for hierarchical ZigBee/IEEE 802.15.4 networks corresponding to realistic situations (less than 50 nodes with a hierarchical routing and many-to-one transmissions) with as main objective the bandwidth improvement. The principal interest of this solution resides in its simplicity and the facility to integrate it in IEEE 802.15.4 devices insofar as the modifications of the MAC layer are light. This solution is efficient: according to the intensity of the traffic, the global throughput is multiplied by a variable factor between 2 and 5 in comparison with the mono-channel solution and with packets loss ratio much smaller. The throughput is also improved by an average factor equal to 2 compared to a random channel allocation or to a simple subtree distribution.

We currently work on several improvements. The first consists in allocating in a centralized way several channels on each link, the selection of the channel being done dynamically starting from the LQI or the RSSI available on CC2420. The second idea consists in improving the CC2420 transceiver packet forwarding process in the case of multihop links.

Besides, the following stage is the implementation and the test of the multichannel solution on our real sensor network platform made up of MicaZ, TelosB and Imotes2.
