Keywords: restoration, deconvolution, 3D images, confocal microscopy, Poisson noise, wavelets

ABSTRACT

We propose in this paper an iterative algorithm for 3D confocal microscopy image restoration. The image quality is limited by the diffraction-limited nature of the optical system which causes blur and the reduced amount of light detected by the photomultiplier leading to a noise having Poisson statistics. Wavelets have proved to be very effective in image processing and have gained much popularity. Indeed, they allow to denoise efficiently images by applying a thresholding on coefficients. Moreover, they are used in algorithms as a regularization term and seem to be well adapted to preserve textures and small objects. In this work, we propose a 3D iterative wavelet-based algorithm and make some comparisons with state-of-the-art methods for restoration.

1. INTRODUCTION

Confocal microscopy 1 is a powerful tool allowing to get an accurate view of cellular physiology, thus explaining its growing use in biological specimen imaging. Biological image quality is limited by two factors: a blur due to microscope optics (modeled by the Point Spread Function (PSF) denoted here by \( h \)), even if it is limited in confocal microscopy with respect to widefield microscopy, and the detection which is done with low photon flow leading to Poisson statistics.

The Richardson-Lucy algorithm 2,3 is often used to restore images in case of Poisson noise because of its well fitting. A regularization term has also been added in order to stabilize the inversion. More recently, some authors proposed to use the wavelet transform 4,5 for biological image deconvolution. In the literature of Poisson noise, many people use a pre-processing like the Anscombe 6 transform or the Fisz transform 7 in order to stabilize the noise variance and to apply more usual methods 8 (i.e. techniques developed for Gaussian noise).

In the biological context, different approaches have been introduced: deconvolution and denoising steps are often splitted and then applied consecutively.

The approach considered here combines, in a unique algorithm, denoising and deconvolution. In this paper we propose a deconvolution method based on a 3D wavelet decomposition and an iterative deconvolution algorithm operating on the wavelet coefficients. We then make a comparative study of the different approaches considered in the biological microscopy context. The organization of the paper is as follows: in Section 2, we present the relevant background in biological microscopy image restoration. Then we introduce wavelets in Section 3 and the proposed algorithm in Section 4. Finally, we will give comparative results in Section 5 both on simulated and real data.

2. BACKGROUND

2.1. Problem context

Image formation model

The considered image formation model is the following:

\[
i = \mathcal{P}(o * h)
\]

where \( i \) is the observed image, \( o \) the original one, \( \mathcal{P}(\cdot) \) stands for Poisson noise and \( * \) denotes the 3D convolution.

We work with 3D objects, both for the images and the PSF (Point Spread Function) which is constructed
following different models (physical PSF, Gaussian PSF...). Image restoration (including both denoising and deconvolution) consists in estimating the original image, thus obtaining \( \hat{o} \), only knowing the observation \( i \) (we assume here that the PSF is known).

**PSF model** The PSF modelizes the microscope optics. We consider here an analytical form of the PSF described by:

\[
h(x, y, z) = |A_R(x, y) * \hat{P}_\lambda_{em}(x, y, z)|^2 |\hat{P}_\lambda_{ex}(x, y, z)|^2
\]  

(2)

The excitation (resp. emission) wavelength is \( \lambda_{ex} \) (resp. \( \lambda_{em} \)).

\( \hat{P}_\lambda \) is the 2D Fourier transform on \( x, y \) of the pupil function \( P_\lambda \), given by\(^9-11\):

\[
P_\lambda(u, v, z) = \Pi z \left( \sqrt{u^2 + v^2} \right) e^{\frac{2\pi i}{\lambda} W(u,v,z)}
\]  

(3)

Here the complex term \( W(u, v, z) = \frac{1}{2} z (1 - \cos 2\alpha) \) is the aberration phase derived from\(^11\). \( \rho = \frac{NA^2}{2\lambda} \) is the lateral cut-off frequency, and \( NA = n_o \sin \alpha \) the numerical aperture which is related to the amount of light entering the microscope and the immersion medium refractive index \( n_o \). The phase \( W \) depends only on the defect of focus. This theoretical model of the confocal PSF does not take into account geometrical (e.g. spherical) lens aberrations and refractive index induced diffraction.

**Noise nature: Poisson statistics** At the same time, we are confronted with Poisson noise. A way to face this problem and use more conventional processing (stabilizing the variance) consists in either:

- applying the Anscombe transform\(^6\). This transformation is defined as follows:

\[
A(i(x, y, z)) = 2 \sqrt{i(x, y, z) + \frac{3}{8}}.
\]  

(4)

- applying the Fisz transform\(^7\). This transformation is defined as follows:

1. Process a non normalized Haar transform.
2. Transform the detail coefficients \( d_{j,m}(k) \) of level \( j \), subband \( m \) and spatial position \( k \) as

\[
d_{j,m}(k) = \begin{cases} 
\frac{d_{j,m}(k)}{\sqrt{a_{j,m}(k)}} & \text{if } a_{j,m}(k) \neq 0 \\
0 & \text{if } a_{j,m}(k) = 0
\end{cases}
\]

where \( a_{j,m} \) denotes the approximation coefficients.
3. Reconstruct using the inverse non normalized Haar transform.

After such transformations, the noise can be asymptotically considered as \( N(0, 1) \).

Some authors\(^12\) make the assumptions of a mixture of Gaussian noise (with mean \( \mu \) and variance \( \sigma^2 \)) and Poisson noise \( P(.) \). They consider the following image formation model:

\[
i = \alpha P(o * h) + N(\mu, \sigma^2)
\]  

(5)

where \( \alpha > 0 \) and develop adapted methods for image restoration problem.

In our case, we consider the noise having Poisson statistics.
2.2. Richardson-Lucy based algorithms

Many approaches are based on the Richardson-Lucy (RL) algorithm\cite{2,3} which is well adapted to Poisson noise.

One iteration of this algorithm is given by:

\[ o_{n+1}(x) = \left\{ \frac{i(x)}{(o_n + h)(x)} \right\} * h(-x) o_n(x). \]

Several regularizations, allowing to stabilize the inversion, have been proposed such as:

**Tikhonov-Miller regularization**\cite{13}

\[ o_{n+1}(x) = \left\{ \frac{i(x)}{(o_n + h)(x)} \right\} * h(-x) \frac{o_n(x)}{1 + 2\lambda_{TM}\triangle o_n(x)^{1+2\lambda_{TM}}}. \]

**Total variation regularization**\cite{14,15}

The algorithm (RL-TV) is thus yielding to:

\[ o_{n+1}(x) = \left\{ \frac{i(x)}{(o_n + h)(x)} \right\} * h(-x) \frac{o_n(x)}{1 - \lambda \text{div} \left( \frac{\nabla o_n(x)}{\| \nabla o_n(x) \|} \right)}. \]

2.3. Separation of the denoising and deconvolution steps

In the microscopy field, researchers often apply deconvolution and denoising steps consecutively, thus introducing some difficulties. We discuss in this part the advantages and drawbacks of the different approaches.

2.3.1. Denoising then deconvolution

The denoising step often corresponds to a wavelet coefficient thresholding using wavelets\cite{4,5} or steerable pyramids\cite{16}. Concerning the deconvolution step, RL algorithm or a MAP (Maximum A Posteriori) method is often used. When Poisson noise is considered, pre-processing stage to stabilize the noise variance is applied previously on the data.

Several drawbacks can be pointed out: we wonder whether the PSF is modified during the denoising step (in\cite{16} they estimate it after denoising); but also, we are not sure of the noise nature after the denoising step. Wavelets have shown to be really efficient in denoising problems, which leads naturally to method 1.

2.3.2. Deconvolution then denoising

The diagram shows the separation of the denoising and deconvolution steps.

**Figure 1.** Scheme of Method 1.

**Figure 2.** Scheme of Method 2.
The deconvolution step often corresponds to an inversion of the PSF\textsuperscript{17} taking into account it may have zeros. A simple way to achieve it is

\[
\mathcal{F}(\hat{o}) = \begin{cases} 
\frac{\mathcal{F}(o)}{\mathcal{F}(PSF)} & \text{if } |\mathcal{F}(PSF)| > \epsilon \\
0 & \text{otherwise}
\end{cases}
\]

where \(\mathcal{F}(,.)\) denotes the Fourier transform. \(\epsilon\) can be taken equal to 0.001.

Concerning the denoising step, it often corresponds to a coefficient thresholding in a transformed domain. The noise level has to be estimated. When Poisson noise is considered, pre-processing stage to stabilize the noise variance is previously applied on the data.

The approach creates an amplification of the noise during the deconvolution step and after the inversion of the PSF, the noise nature is not known. The second step (denoising) must take into account this particularity.

This method is easy to implement and comes naturally to mind. Nevertheless, without an adaptation and a careful implementation,\textsuperscript{18} the noise is too strongly amplified and this method gives rise to bad results.

In order to tackle the different problems above mentioned, we propose to combine the denoising and deconvolution steps using a single algorithm operating in the 3D transformed domain, as we will see later.

### 3. 3D WAVELET ANALYSIS

This section aims at giving a brief recall of the 3D wavelet transform. We also propose here an anisotropic version of the transform.

\[
\begin{array}{c}
\text{Figure 3. Analysis filter bank for a 3D Discrete Wavelet Transform.} \\
\end{array}
\]

The classical 3D dyadic wavelet analysis of \(L^2(\mathbb{R})\) involves one scaling function \(\psi_0 \in L^2(\mathbb{R})\) and a mother wavelet \(\psi_1 \in L^2(\mathbb{R})\) such that:

\[
\forall m \in \{0,1\}, \quad \frac{1}{\sqrt{2}} \psi_m(t) = \sum_{k=-\infty}^{\infty} h_m[k] \psi_0(t-k),
\]

where \((h_m[k])_{k \in \mathbb{Z}}\) are real-valued square summable sequences. The analysis filter bank presented in Fig. 3 itered on the lowpass coefficients allows to realize the multiresolution analysis. Another specification of confocal microscopy is the difference of resolution in the \(z\) direction compared to the \((x,y)\) directions. A way to tackle this problem would be to consider an anisotropic decomposition. By anisotropic, we mean to make a different processing (i.e. better adapted) in the \(z\) direction. We propose here to use a different wavelet in the \(z\) direction (as the decomposition is separable) and also to consider a different resolution level (lower). This is equivalent in Fig. 3 to use different filters in the \(z\) direction compared to the \(x\) and \(y\) directions.
and stop the multiresolution analysis earlier for the z direction.
The coefficients obtained after such an analysis will be processed as presented in the next section.

4. PROPOSED ALGORITHM

We study here an iterative 3D wavelet-based algorithm\textsuperscript{19–21} allowing to operate conjointly denoising and de-convolution in the wavelet transform domain, considering the 3D Discrete Wavelet Transform presented in the previous section. The objective is to:

\[
\min_{o \in H} \frac{1}{2} \|h * o - i\|^2 + \sum_{k \in K} \phi_k((o | e_k)).
\]  

(10)

This criterion is composed of two terms: a data fidelity term and a regularization term (which penalizes each wavelet coefficients) where the regularization function \(\phi_k\) can be chosen adaptively.

The algorithm reads:

\[
o_{n+1} = o_n + \lambda_n (\text{prox}_{\gamma_n \phi_k} < o_n + \gamma_n (h^*(i - ho_n))e_k > -o_n)
\]

(11)

where \(e_k\) stands for an orthonormal basis and prox denotes the proximity operator. Some properties of this operator as well as the convergence property of this algorithm are given in\textsuperscript{21}.

For instance, we can choose:

\[
\phi = \omega |\cdot | \\
\phi = \omega |\cdot |^2
\]

(12) (13)

where \(\omega\) is a fixed parameter and \(\phi\) a fixed regularization function. When \(\phi\) is defined by (12), then the corresponding \(\text{prox}_{\omega}\) is a soft thresholding with threshold \(\omega\). We take \(\gamma = 1.99\) (step size) and \(\lambda = 1\) (relaxation parameter) in the numerical experiments.

This algorithm is directly applied to the coefficients issued from a 3D wavelet transform. When Poisson noise is considered, we apply a pre-processing on the data (Anscombe or Fisz), because this algorithm has been developed for Gaussian noise.

5. COMPARATIVE RESULTS

5.1. Initial definitions

In order to evaluate the quality improvement, we propose to use the I-divergence measure. The I-divergence\textsuperscript{22} between two 3D images \(o\) and \(\tilde{o}\) is given by:

\[
I_{o,\tilde{o}} = \sum_{ijk} \left\{ o_{ijk} \ln \left( \frac{o_{ijk}}{\tilde{o}_{ijk}} \right) - (o_{ijk} - \tilde{o}_{ijk}) \right\}
\]

(14)

5.2. Tested images

We propose here to proceed the tests on simulated, phantom and real data.

**Synthetic image** The first kind of data allows us to evaluate the proposed method performances in terms of qualitative but also quantitative measures. We suppose we know the original image and we add blur and noise in order to obtain the observed data. The original and degraded data are represented in Fig. 4.

We assume the microscope has a perfect pinhole and its characteristics are the following:

- The magnification of the objective is 63\(\times\).
- The refractive index of the medium is 1.33 and of the immersion lens medium (oil) is 1.518.
• The numerical aperture is 1.4 airy units.
• The excitation wavelength is 488nm whereas the emission wavelength is 520nm.
• The voxel size is 0.02µm × 0.02µm × 0.05µm.

**Phantom image**  We consider here a spherical shell (as represented in Fig. 5) of diameter 15µm and which thickness is known to lie between 0.5µm and 0.7µm.

The acquisition is made using a microscope having the following parameters:

• The magnification of the objective is 63×.
• The refractive index of the medium is 1.33 and of the immersion lens medium (oil) is 1.518.
• The numerical aperture is 1.4 airy units.
• The excitation wavelength is 488nm whereas the emission wavelength is 520nm.
• The voxel size is 89.26nm × 89.26nm × 232.75nm.

The 3D image consists in 128 stacks of size 256 × 256 and one xy slice of the obtained image is shown in Fig. 7 (left). The objective is, knowing the original object size, to recover it after restoration process.

![3D synthetic image. Original (left) and degraded (right).](image)

![Spherical shell of diameter 15 µm.](image)
Real image  We also work with real 3D confocal microscopy images.

We consider here an image which consists in 30 stacks representing a regenerating mammalian skin (see Fig. 6). The acquisition parameters are the following:

- Microscope Zeiss Axiovert 200
- The magnification of the objective is 40×.
- The refractive index of the medium is 1.33 and of the immersion lens medium (oil) is 1.518.
- The numerical aperture is 1.3 airy units.
- The excitation wavelength is 488nm whereas the emission wavelength is 520nm.
- The pinhole size is equal to 71µm
- The voxel size is 0.45µm × 0.45µm × 1µm.

5.3. Tested methods

Method 1:
1. Pre-processing
2. Wavelet denoising
3. Inverse Pre-processing
4. RL algorithm

Method 2:
1. PSF inversion
2. Noise estimation
3. Wavelet denoising

Method 3:
1. Pre-processing
2. Deconvolution + denoising
3. Inverse Pre-processing
On the one hand, when the noise is estimated (for example, after the PSF inversion in method 2), we use the robust median estimator which leads to the estimated variance \( \hat{\sigma} \) of \( \sigma \) considering the first level detail wavelet coefficients \( d_{1,(2,2)} \):

\[
\hat{\sigma} = \frac{1}{0.6745 \text{median}(|d_{1,(2,2)}|)}.
\]

(15)

On the other hand, when the noise is Poisson, we apply the Anscombe transform (see Section 2) in order to stabilize its variance to 1.

5.4. Quantitative and qualitative results

**Synthetic image** We propose, first, to give some numerical results comparing the three proposed methods. These preliminary tests allow us to calibrate the parameters. We consider symlets wavelets of length 16. For method 1, Sureshrink\(^{24}\) thresholding is applied followed by the RL algorithm. For method 2, we invert the PSF as described by (9) with \( \epsilon = 0.001 \), then make an estimation of the noise level (using the robust median estimator) and apply Sureshrink thresholding. Concerning method 3, \( \phi = 0.15 \). | and in the anisotropic case, we replace the z wavelet by the Haar wavelet. In all cases, we choose the Anscombe transform as pre-processing stage.

Table 1. Restoration results (I-divergence) considering Poisson noise on the synthetic image.

As predicted, method 2 does not lead to good numerical results because it has to be better adapted. The anisotropic form of the wavelet transform allows to improve the I-divergence. The first approach also allows to obtain good results.

**Phantom image** The objective here is to recover the initial shell dimension.

In Fig. 7, we represent the original data (left) the restored data using method 1 (center) and the restored data using method 3 (right). It seems that method 3 leads to a reduced thickness. Let’s have a look to the intensity profile represented in Fig. 8. The observed data gives approximately a thickness of 1.2\(\mu m\) whereas method 1 leads to 1\(\mu m\) and method 3 to 0.76\(\mu m\). The two first measurements are too large and the third one is a little bit too large but it better approximates the reality which means that method 3 allows to better recover the initial shell size.

Figure 7. Restoration of the shell. Raw data (left), restored images using method 1 (center) and method 3 (right).
Figure 8. Intensity profile of the 3 $xy$ images represented in Fig. 7. 1 pixel represents 89nm.

**Real image**  Now, we are interested in 3D real image restoration. The obtained results can be judged and evaluated visually.

In Fig. 9, we have represented two slices of the 3D image shown in Fig. 6. The right column corresponds to the restored images; the first impression can be mitigated but a careful look to these images allows to notice some improvements. In the upper left corner, we can see in the stack, the vitelline membrane which is considered as noise and alveolus structures which correspond to the central cells. In the upper right corner we have the restored image: the vitelline membrane has been removed and some central cells are recovered from noise. In the lower right corner, we can distinguish some filaments in the image which correspond to epidermal cells. In the associated restored image, a part of the noise has been removed allowing to recover some central cells and to better see epidermal cells.

**6. CONCLUSION AND PERSPECTIVES**

We have presented, in this paper, different image restoration methods for 3D confocal microscopy images based on wavelets. More sophisticated analyses such as the Dual-tree Wavelet Transform\(^{25,26}\) could improve these restoration results at a price of a low redundancy.

Concerning the presented methods, the hyperparameters have been fixed empirically until now. An objective would be to compute them adaptively\(^{27}\). The main idea we want to follow in the future is to develop directly Poisson statistic adapted methods.

**7. ACKNOWLEDGMENTS**

The authors want to thank J.-C. Olivo-Marin and B. Zhang (Pasteur Institute, France), Z. Kam (Weizmann Institute, Israel) and Arie Feuer (Technion, Israel), P. Pankajakshan (INRIA Sophia-Antipolis, France) for several interesting discussions.

We would like to thank Pasteur Institute and Nice University (UMR 6543 CNRS / Institute of Signaling, Developmental Biology and Cancer) for providing us the spherical shell images and the mammalian regenerating skin images, respectively. This research was partly supported by the P2R Franco-Israeli Collaborative Program. The first author would like to thank INRIA for funding her Post-doc fellowship.
