(Received 25 June 2009; accepted 9 October 2009; published online 4 November 2009)

Isofulminic acid, HONC, the most energetic stable isomer of isocyanic acid HNCO, higher in energy by 84 kcal/mol, has been detected spectroscopically by rotational spectroscopy supported by coupled cluster electronic structure calculations. The fundamental rotational transitions of the normal, carbon-13, oxygen-18, and deuterium isotopic species have been detected in the centimeter band in a molecular beam by Fourier transform microwave spectroscopy, and rotational constants and nitrogen and deuterium quadrupole coupling constants have been derived. The measured constants agree well with those predicted by ab initio calculations. A number of other electronic and spectroscopic parameters of isofulminic acid, including the dipole moment, vibrational frequencies, infrared intensities, and centrifugal distortion constants have been calculated at a high level of theory. Isofulminic acid is a good candidate for astronomical detection with radio telescopes because it is highly polar and its more stable isomers (HNCO, HOCN, and HCNO) have all been identified in space. © 2009 American Institute of Physics. [doi:10.1063/1.3257680]

I. INTRODUCTION

Isocyanic acid and its isomers have long attracted organic chemists because they are composed of the four most important biogenic elements of organic chemistry, and because they provide interesting tests of chemical bonding and electronic structure. The isocyanic acid isomers have been the subject of theoretical and experimental studies since the 16th century. Although many isomeric arrangements are possible, only four are minima on the potential energy surface: isocyanic acid HNCO, cyanic acid HOCN, fulminic acid HCNO, and isofulminic acid HONC. All have singlet electronic ground states, linear or nearly linear heavy-atom backbones, and planar equilibrium structures. Recent calculations predict that HOCN, HCNO, and HONC lie, respectively, 24.7, 70.7, and 84.1 kcal/mol higher in energy than HNCO. All are calculated to be highly polar molecules, with dipole moments from 1 to 3.5 D.

The isocyanic acid isomers are of astronomical interest. Isocyanic acid itself was one of the first molecules identified in the interstellar gas on the basis of the prior laboratory microwave spectroscopy. It has now been found in many locations, including over sixty galactic sources and nine external galaxies. On the basis of recent laboratory data, there is now evidence for cyanic acid in the Galactic center source Sgr B2, at about the same time, Marcelino et al. observed radio lines of the third most stable isomer, fulminic acid, in three starless cores and in the low-mass star forming region L1527. The presence of higher-lying isomers in hot cores and other warm regions may result from reactions on the surfaces of interstellar dust grains. If so, the isocyanic isomers may provide a useful tool to estimate relative contributions of gas-phase and grain chemistry.

Until quite recently, only isocyanic acid and fulminic acid had been detected at high spectral resolution in the gas phase. The rotational and vibrational spectra of both have now been thoroughly studied, motivated partly by a desire to understand the quasilinear structure produced by the large-amplitude bending motion. The second most stable isomer, cyanic acid HOCN, was first detected at low temperature in an inert matrix after ultraviolet irradiation of HNCO and yielded a weak feature near the predicted frequency of the rotational transition of HONC, without confirming lines. No lines attributable to HOCN were observed. During the past year, cyanic acid has been detected in the gas phase, and its microwave rotational spectrum measured.

Until the present work, there was no conclusive evidence for the remaining isomer, isofulminic acid HONC. Maier et al. reported a low temperature infrared matrix spectrum in argon, but the assignment was subsequently withdrawn. There have been at least two attempts to produce HONC by pyrolysis of mercury fulminate and other compounds; the first by Wentrup et al. only produced HCNO and trace amounts of HNCO; the second by McNaughton and Evans yielded a weak feature near the predicted frequency of the rotational transition of HONC, without confirming lines. No lines attributable to HOCN were observed.

From theoretical self-consistent field (SCF) calculations of the potential energy surface of the isocyanic isomers, Poppinger et al. and McLean et al. concluded that isofulminic acid...
acid is stable enough to exist in the interstellar gas. Poppinger et al.26 also examined substituted isocyanic acid isomers, in particular the stability of the lesser known RONC isomers, first experimentally observed by Wentrup et al.27 three years later. Pinnavaia et al.3 used a perturbational approach to calculate spectroscopic parameters of HONC from a quartic internal coordinate force field determined by second order Möller–Plesset theory. Isomerization and fragmentation pathways for the CHNO system were studied by Mebel et al.28 with density functional theory, by Ding et al.29 with the complete active space method, and by Schuurman et al.5 with several coupled cluster approaches. The equilibrium geometry and energetics of the four most stable isocyanic isomers were recently analyzed in significant detail by some of the present authors with the all electron coupled cluster singles and doubles with perturbative triple excitations, CCSD(T) method, in combination with large correlation consistent bases.6,30 The computed barriers to linearity from all electron CCSD(T)/aug-cc-pCVQZ calculations are 5.3 kcal/mol (1839 cm−1) for HNCO, 26.9 kcal/mol (9406 cm−1) for HOCN, and 47.9 kcal/mol (16761 cm−1) for HONC, whereas the equilibrium structure of HCNO was calculated to be linear. In addition, HOCN, HCNO, and HONC were found to lie 24.5 kcal/mol (8577 cm−1), 70.0 kcal/mol (24467 cm−1), and 84.2 kcal/mol (29464 cm−1) above the most stable HNCO molecule, in good agreement (to 0.2 kcal/mol) with the earlier frozen-core focal-point analysis results of Schuurman et al.5 Minimum energy paths along the angular coordinates were used in combination with the dominant kinetic energy contributions to predict their key rovibrational spectroscopic features.30 The harmonic heavy-atom bending frequency ωb and the harmonic torsional frequency ωT of HONC were identified as the lowest among all of the four stable CHNO isomers.6,30 Their electric and magnetic properties were studied in Ref. 7, where both a Mulliken population analysis of the total electron density and molecular orbitals were used to interpret the changes in the electronic structure properties.

Motivated by the recent gas-phase detection of cyanic acid15 and coupled cluster calculations,6,7,30 a combined experimental and theoretical effort has been undertaken to spectroscopically characterize the most energetic isomer, isofulminic acid. Here we report the laboratory detection of the fundamental rotational transition of HONC in a supersonic molecular beam by Fourier transform microwave (FTM) spectroscopy. Our identification has been confirmed by detection of the same transition in the carbon-13, oxygen-18, and deuterium isotopic species, with the expected nitrogen hyperfine structure. A number of other spectroscopic quantities including equilibrium and ground state rotational constants, dipole moments, anharmonic vibrational frequencies, infrared intensities, and centrifugal distortion constants have also been calculated theoretically for HONC and its rare isotopologues.

II. THEORETICAL CALCULATIONS

Ab initio calculations have been carried out for the ground A′ electronic state by means of the coupled cluster electron correlation method CCSD(T) including all single and double excitations and a perturbative term for connected triple substitutions, as implemented in the Mainz–Austin–Budapest version of the ACES2 program package.31 Dunnings’s correlation consistent polarized core valence basis sets, commonly termed cc-pCVXZ, have been used.32,33 HONC possesses a planar equilibrium structure of trans type.7 In C4 symmetry, the reference electronic configuration used in the SCF approximation to construct molecular orbitals is given by

\[(\text{core})^6(4a')^2(5a')^2(6a')^2(7a')^2(1a'')^2(8a')^2(9a')^2(2a'')^2,\]

where the core contribution \((1a')^2(2a')^2(3a')^2\) contains the three 1s-like core orbitals located on oxygen, nitrogen, and carbon, respectively. The highest occupied molecular 2a″ orbital is primarily composed of the out-of-plane \(2p_z\) atomic orbitals of O, C, and N, as depicted in Fig. 1, where a lone electron pair on oxygen may easily be noted. The dominant single determinant reference character is confirmed by a \(T1\) diagnostic value near 0.014 and largest \([T2]\) amplitudes smaller than 0.07 in our all electron CCSD(T) calculations.

A. Equilibrium geometry

Large-scale coupled cluster CCSD(T) all electron results for the equilibrium structure of HONC were reported in a recent study on the CHNO isomer family.30 There the geometrical parameters at the complete basis set (CBS) limit, computed for the cc-pCVXZ and aug-cc-pCVXZ basis set families by means of the simple three-parameter exponential extrapolation, showed excellent agreement within 0.0003 \(\text{Å}\), 0.02° \(\angle\text{(O NC)},\) and 0.07° \(\angle\text{(HON)}\). The best estimate for the heavy atom ONC bond angle of 172.56°, introduced in Ref. 30 as the mean value of the two respective CBS results, is employed in the present work in combination with the CCSD(T)/cc-pCVXZ bond lengths and the mean value of 104.92° for the HON angle, where \(\approx\) denotes the CBS limit. The latter set of geometrical parameters is displayed in Fig. 2 and will be referred to as the best estimate geometry. For quantities computed at this geometrical arrangement, we use the superscript \(\approx\) throughout this paper.

The NC bond length in Fig. 2 is only 0.004 Å longer than \(r(\text{NC})\) of 1.169 Å in HNCO,34 indicating a similar type of bonding (\(\text{N}^+ = \text{C}\)) in the two molecules. This is in accord with a partial atomic charge (\(\delta\)) distribution found to be

FIG. 1. Highest occupied molecular 2a″ orbital of HONC. The contour surfaces of orbital amplitude 0.025 and −0.025 are shown.
lies rather close to the H-O-N-C chain from the atomic population analysis of the CCSD(T)/cc-pCV5Z density (see Sec. II D). One may also note that the H-O-N angle in Fig. 2 compares well with the H-O-H angle of 104.45° in H$_2$O, what presumably points at a similar spatial electron distribution around oxygen in HONC and H$_2$O.

The principal inertial axis in Fig. 2 lies rather close to the nearly linear heavy-atom ONC backbone of the molecule, rotated only 4.8° from the N-O bond. The CCSD(T)/cc-pCV5Z dipole moment vector for the best estimate structure has a magnitude of $|\mu|=3.487$ D. This value is somewhat smaller than $|\mu|=3.815$ D for HOCN and larger than $|\mu|=3.340$ for HCNO and $|\mu|=2.073$ D for HNCO, calculated at the same CCSD(T)/cc-pCV5Z level of theory. In addition, $|\mu|$ of HONC is somewhat larger than the CCSD(T)/aug-cc-pCVQZ dipole moment of 3.110 D calculated here for HNC. The experimentally derived $|\mu|$ values for HNCO, HCNO, and HNC are 2.075 D (Ref. 36), 3.350 D (Ref. 37), and 3.050 D (Ref. 38), respectively.

**B. Spectroscopic parameters**

Zero point vibrational corrections to rotational constants could be computed only at the CCSD(T)/cc-pCVTZ level due to technical limitations. The equilibrium rotational constants calculated from the CCSD(T)/cc-pCVTZ optimum geometry reported previously and from the best estimate structure of Fig. 2 are collected for the five HONC isotopologues in Table I. The former set of constants is denoted by $A_e^{(0)}, B_e^{(0)}, C_e^{(0)}$, whereas we use $A_e^{(0)}, B_e^{(0)}, C_e^{(0)}$ to designate the latter results. As seen, HONC is an almost prolate symmetric top with an asymmetry parameter $\kappa$ of $-0.9994$. The ground-state rotational constants $A_0^{(3)}, B_0^{(3)}, C_0^{(3)}$ and ground-state vibrational corrections $\Delta A^{(3)}, \Delta B^{(3)}, \Delta C^{(3)}$ are both obtained from the CCSD(T)/cc-pCVTZ calculations carried out at the CCSD(T)/cc-pCVTZ optimum geometry. The ground-state vibrational corrections are computed from the cubic and semidiagonal quartic force field in a normal coordinate representation by means of vibrational second-order perturbation theory.

The ground-state rotational constants for the best CCSD(T) estimate structure are obtained from $A_e^{(0)}, B_e^{(0)}, C_e^{(0)}$ and the ground-state CCSD(T)/cc-pCVTZ vibrational corrections according to

**FIG. 2.** *Ab initio* equilibrium structure, principal $a,b$ moment-of-inertia axes and dipole moment vector $\mu$.

---

**TABLE I.** Experimental and theoretical rotational constants. Equilibrium rotational constants $A_e, B_e, C_e$, ground-state rotational constants $A_0, B_0, C_0$, and ground-state vibrational corrections $\Delta A, \Delta B, \Delta C$ are calculated from the CCSD(T)/cc-pCVTZ optimum structure (superscript 3) and the best CCSD(T) estimate structure (superscript 0). The experimentally derived rotational constants $B_{eff}$ for the $K_z=0$ ladder are highlighted by bold numbers. The numbers in parentheses given along with the experimental values are the estimated uncertainties (1σ) in units of the last significant digit. For the definition of $B_{eff}^{(0)}$ and $\Delta(B_{eff})$, see Eqs. (2) and (3). All quantities are given in megahertz.

$A_0^{(\nu,3)} = A_0^{(\nu)} - \Delta A^{(3)},$ \hspace{1cm} (1)

and by analogy for $B$ and $C$. For comparison with the experimental results $B_{\text{eff}}$ reported in Table I, we introduce the average value $\overline{B}_{\text{eff}}^{(\nu,3)}$,

$$\overline{B}_{\text{eff}}^{(\nu,3)} = [B_0^{(\nu,3)} + C_0^{(\nu,3)}]/2,$$ \hspace{1cm} (2)

and the deviation $\Delta B_{\text{eff}}$,

$$\Delta(B_{\text{eff}}) = \overline{B}_{\text{eff}}^{(\nu,3)} - B_{\text{eff}}$$ \hspace{1cm} (3)

of the theoretical results $B_{\text{eff}}^{(\nu,3)}$ from the experimental counterparts $B_{\text{eff}}$. Table I shows that the $ab$ initio rotational constants agree very well with the experimentally determined values, exhibiting $\Delta(B_{\text{eff}})$ of 12–14 MHz (approximately 0.1%) for the HONC isotopologues.

In Table II, we summarize the harmonic $\omega_i$, frequencies, the fundamental $\nu_i$ frequencies computed from the anharmonic force field by second order perturbation theory, and the infrared intensities derived within the double harmonic approximation. Table III provides the centrifugal distortion constants in Watson’s $S$ reduction. These two tables furnish additional information, potentially useful for future high-resolution rotational spectroscopic studies on vibrationally excited HONC.

In accord with Table II, the most intense infrared transitions are to be expected in the region of the stretching $\nu_1$(H–O) frequency, followed by the $\nu_3$(H–O–N bend) transition of an almost halved intensity. The $(\nu_3, \nu_6)$ wave number pair for the heavy-atom bending $\nu_3$ mode and the torsional $\nu_6$ mode calculated to be (321 cm$^{-1}$, 273 cm$^{-1}$) for HONC is smaller than both (576 cm$^{-1}$, 650 cm$^{-1}$) for HNCO and (448 cm$^{-1}$, 504 cm$^{-1}$) for HOCN. Although the $\nu_3$ and $\nu_6$ modes of HONC possess a very low infrared spectral intensity in Table II, they are important in both the overall internal dynamics of real vibrating and rotating HONC (due to angular momentum conservation) and in the kinetic behavior (due to their major contribution to the number and density of states).

The vibrational $\nu_1$ and $\nu_3$ modes involve hydrogen and are sensitive to deuteration, see Table II. The intensity ratio $R_{\nu_1} = I_{\text{DO}}/I_{\text{HO}}$ of 0.50 for $\nu_1$ readily indicates the highly localized nature of the OH(D) vibration. This can be demonstrated as follows. Making use of the normal coordinate $Q_{XY}$ of the X-Y vibration written as $\sqrt{M_{XY}}(X-Y)$ in the local mode picture, where $M_{XY}$ is the reduced mass and $r(X-Y)$ the internal coordinate, we may rewrite the intensity ratio

TABLE III. Centrifugal distortion constants (in megahertz) of Watson’s $S$-reduced Hamiltonian, obtained from the CCSD(T)/cc-pCVTZ calculations by the use of perturbation theory.

\[ R_{v_1} = \frac{\varepsilon_2}{\varepsilon_1} \frac{R_{v_1}}{\varepsilon_1^2 - \varepsilon_1^2} \]  

in the local mode limit as

\[ I^{\text{loc}} R_{v_1} = M_{\text{HO}}/M_{\text{DO}} = m_\text{H} m_\text{DO}/m_\text{O} m_\text{H} \approx 0.53, \]

where \( m_\text{X} \) and \( m_\text{XY} \) denote the mass of X and XY, respectively. The theoretical \( R_{v_1} \) value of 0.50 for HONC closely resembles the expected local mode result \( I^{\text{loc}} R_{v_1} \). Based on similar arguments and the bond-distance-bond-angle expression of the reduced mass for the bending vibration, we obtain \( R_{v_3} = 0.63 \) and \( I^{\text{loc}} R_{v_3} = 0.57 \) for \( v_3 \), indicating a predominant local mode nature also for this bending mode. Inclusion of anharmonic contributions of the potential energy, in particular coupling with \( v_2 \) and \( v_4 \), may lead to a less localized character of \( v_3 \); this can influence spectral intensities in the case of strong anharmonic resonances.

Pinnavaia et al. suggested for the main isotopologue HONC a Fermi resonance of \( v_2 \) with 2\( v_4 \), a Coriolis resonance between \( v_4 \) and \( v_5 \), and a Darling–Dennison resonance of \( v_5 \) with \( v_6 \). In contrast, our \textit{ab initio} calculations for the five HONC isotopologues leave room for a Fermi resonance of \( v_2 \) with 2\( v_4 \) only for DONC.

The centrifugal distortion constant \( D_J \) of 5.8 kHz for HONC in Table III is somewhat larger than \( D_J = 3.4 \) kHz for HNCO and \( D_J = 4.1 \) kHz for HCON, obtained at the same CCSD(T)/cc-pCVTZ level of theory.\cite{46} The constant \( D_K \) of 325 MHz for HONC is larger than \( D_K = 254 \) MHz for HOCN,\cite{40} but much smaller than the experimentally derived value \( D_K = 5940 \) MHz for HCON, known to be quasi-planar.\cite{42} The value of \( D_K \) is primarily defined by the quartic centrifugal distortion constant \( \tau_{\text{aniso}} \), found to be \(-1303\) and \(-176 \) MHz for, respectively, HONC and DONC, such that a decrease in \( D_K \) by a factor of 7.5 upon deuteration appears quite reasonable.

### C. Nuclear quadrupole coupling constants

The nuclear quadrupole coupling constants \( \chi_{ij} \) for the \( ^{14}\text{N}(I=1) \) and D(I=1) nuclei are computed at the CCSD(T)/cc-pCVTZ level of theory for the best CCSD(T) structure of Fig. 2. These results are collected in Table IV. The theoretical results for \( \chi_{ij} \) are not vibrationally averaged. Nuclear quadrupole coupling constants computed for HONC at the optimum CCSD(T)/cc-pCVTZ geometry were already reported in Table 2 of Ref. 7. The latter structure and the best CCSD(T) estimate structure of Fig. 2 agree within 0.0003 \( \text{Å} \) and 0.06\%,\cite{30} yielding nuclear quadrupole constants that agree within 1 kHz.

At the site of a specific nucleus A, the electric field gradient tensor \( q_{ij} \) in the principal \( a, b, c \) axis system was computed first. The multiplication of the \( q_{ij} \) components by the nuclear quadrupole moment \( Q(A) \) of the nucleus A provides the quadrupole coupling tensor \( \chi \),

\[ \chi_{ij}(A) = [eQ(A)/\hbar]q_{ij}(A), \]

at the site of A for \( i,j = a, b, c \), where \( e \) and \( h \) denote the elementary charge and Planck’s constant, respectively. The tensors \( \chi \) and \( q \) are symmetric and traceless, such that e.g., \( \chi_{ii} + \chi_{ij} + \chi_{kk} = 0 \) holds. From Eq. (6), we obtain

\begin{table}
\centering
\begin{tabular}{|c|c|c|c|c|}
\hline
Property & HONC & DONC & HON\text{\scriptsize{C}} & H\text{\scriptsize{14ONC}} \\
\hline
\( \chi_{ii}(^{14}\text{N}) \) & 3.267(4) & 3.238(5) & 3.268(4) & 3.271(4) \\
\hline
\( \Delta \chi_{aa} \) & 0.028 & 0.0 & -0.003 & -0.003 \\
\hline
\( \chi_{ab}(^{14}\text{N}) \) & -1.370 & -1.370 & -1.370 & -1.570 \\
\hline
\( \chi_{cd}(^{14}\text{N}) \) & 1.5 & 0.0 & 0.2 & 0.2 \\
\hline
\( \theta(\alpha,\alpha) \) & 174.7 & 173.2 & 174.7 & 174.9 \\
\hline
\( \theta(\alpha,\text{DO}) \) & 0.4 & 0.4 & 0.4 & 0.4 \\
\hline
\end{tabular}
\end{table}

\[ \chi_{ij}(^{14}\text{N}) \] [MHz] = 4.802 68 \( q_{ij}(^{14}\text{N})|E_b/\hbar_0|^2 \] (7) and

\[ \chi_{ij}(\text{D}) \] [MHz] = 0.672 00 \( q_{ij}(\text{D})|E_b/\hbar_0|^2 \] (8) using \( Q(^{14}\text{N}) = 2.044 \) fm\(^2\) and \( Q(\text{D}) = 0.286 \) fm\(^2\), both taken from a “year-2008” compilation of the known spectroscopic nuclear quadrupole moments by Pyykkö.\cite{43}

The diagonalization of the nuclear quadrupole coupling tensor yields the eigenvalues \( \chi_{aa} \), \( \chi_{bb} \), and \( \chi_{gg} \) defined such that \( |\chi_{aa}| \geq |\chi_{bb}| \geq |\chi_{gg}| \), which provide the asymmetry parameter \( \eta \) introduced as

\[ \eta = (\chi_{gg} - \chi_{bb})/\chi_{aa}. \] (9)

The latter parameter quantifies the deviation from a cylindrical charge distribution about a specific nucleus. At the site of nitrogen, the eigenvalues of the tensor \( \chi \) are calculated to be \( \chi_{aa}(^{14}\text{N}) = 3.268 \) MHz, \( \chi_{bb}(^{14}\text{N}) = -1.898 \) MHz, and \( \chi_{gg}(^{14}\text{N}) = -1.370 \) MHz, giving thus \( \eta(^{14}\text{N}) = 0.16 \). For deuterium, we obtain eigenvalues of \( \chi_{aa}(\text{D}) \) = 0.287 MHz, \( \chi_{bb}(\text{D}) = -0.172 \) MHz, and \( \chi_{gg}(\text{D}) = -0.115 \) MHz, such that \( \eta(\text{D}) = 0.20 \). Nonzero values of \( \eta \) are characteristic of nonlinear bonds.

In Table IV, we also provide the angle \( \theta(\alpha,\alpha) \) between the inertial \( a \) axis and the principal quadrupole \( \alpha \) axis, as well as the angle \( \delta_{aa} \) between the \( a \) axis of HONC and the \( a \) axis of its isotopologues. The angles \( \theta(\alpha,\text{DO}) \) and \( \theta(\alpha,\text{HO}) \) of the principal quadrupole \( \alpha \) axis with the bond distance vectors \( \text{DO} = \text{DO} - \text{O} \) and \( \text{DO} = \text{DO} - \text{O} \) are listed for the \( ^{14}\text{N} \) and D case, respectively. As seen in the table, the principal \( \alpha \) axis almost coincides with \( \text{DO} \) in the case of \( ^{14}\text{N} \) and with \( \text{DO} \) in the case of deuterium.

In Table IV, the theoretical values for \( \chi_{aa} \) agree with the experimental results \( \exp \chi_{aa} \) within 42–44 kHz for the \( ^{14}\text{N} \)
nucleus and within 7 kHz for deuterium. One may additionally note that the experimental and theoretical findings show the same trend with respect to the main species, $\text{H}^{16}\text{O}^{14}\text{N}^{12}\text{C}$, as seen with the help of
\[
\Delta \chi_{aa} = \chi_{aa}(\text{HONC}) - \chi_{aa}(\text{isotope}).
\]
The theoretical $\Delta \chi_{aa}$ values of 28, 0, and $-3$ kHz for nitrogen are in excellent agreement with the experimental $\Delta \chi_{aa}$ results of 29, $-1$, and $-4$ kHz obtained for, respectively, DONC, HON$^{13}\text{C}$, and H$^{18}\text{ONC}$.

The magnitude of the nitrogen nuclear quadrupole coupling constant $\chi_{aa}(\text{N})$ for HONC is larger than the respective values of 2.114, 2.872, and 0.245 MHz found for HNCO, HOCN, and HCNO, respectively. The principal quadrupole component $\chi_{aa}(\text{N})$ is negative for HONC; to be compared with $-1.559$, 0.795, and $-0.147$ MHz for HNCO, HOCN, and HCNO, respectively. The nuclear quadrupole constants of HONC are now compared with the corresponding values for HNC. A recent theoretical CCSD(T)/cc-pCVTZ result for the equilibrium $\chi_{aa}(\text{N})$ of HNC is given as 0.353 MHz. Our CCSD(T)/aug-cc-pCVQZ value for this molecule amounts, however, to $\chi_{aa}(\text{N})=0.317$ MHz, whereas we obtain $\chi_{aa}(\text{D})$ of 0.279 MHz. In any case, we see that the equilibrium nuclear quadrupole constants for HONC appear to be one order of magnitude larger than those of HNC, exhibiting also a different sign in the case of $\chi_{aa}(\text{D})$. For the ground vibrational state of HNC, Wong computed $\chi_{aa}(\text{N})$ of 0.296 MHz, which is thus by approximately 60 kHz (16\%) smaller than his equilibrium result due to vibrational averaging. The experimentally derived $\chi_{aa}(\text{N})$ and $\chi_{aa}(\text{D})$ values for the ground vibrational state of HNC are reported to be 0.264 MHz and 0.262 MHz, respectively.

In the case of nonlinear HONC, vibrational averaging may be expected to play a somewhat less important role since HONC possesses a pronounced barrier to linearity of ca. 16 700 cm$^{-1}$, as seen in Fig. 3 of Ref. 30, which shows the CCSD(T)/cc-pVQZ minimum energy path (MEP) along the bond angle HON of HONC. The variation of $\chi_{aa}(\text{N})$ along this MEP depicted in Fig. 3 shows a steep increase of more than 1 MHz in $\chi_{aa}(\text{N})$ upon straightening of the bending angle involving hydrogen. One-dimensional calculations carried out for $\beta$ in the framework of the orthogonal diatom-diatom description of the internal molecular geometry give an estimate of $+15$ kHz (0.5\%) for the ground-state vibrational correction to $\chi_{aa}(\text{N})$ due to this bending mode. The heavy-atom bending vibration does not contribute much to the vibrational averaging, since $\chi_{aa}(\text{N})$ exhibits only a negligible variation of several kilohertz along the corresponding minimum energy path. More details on these calculations will be published elsewhere.

D. Electron density

The nuclear quadrupole coupling constant is the spectroscopic measure of the interaction between the nuclear quadrupole moment and the molecular electric field gradient at the specific nuclear site. To qualitatively understand this effect, as well as a possible binding mechanism, several results regarding the electron subspace of HONC are presented here. For more details on this topic, see Ref. 7.

The individual basis function (orbital) populations are given in Table V, where $p_x$ and $p_y$ are the in-plane $p$ orbitals, whereas $p_z$ stands for the out-of-plane functions. The table clearly shows a decrease in the $p_x$ and $s$ characters and an increase in the $p_x$ and $p_y$ characters for both nitrogen and oxygen with respect to the free atom situation. This is an indication of a hybridization involving $p$ orbitals ($\pi$ type binding). Although the orbital population at the carbon center is almost unchanged with respect to free C, a small increase of 0.08 electrons for $p_z$ of C indicates some $sp$ hybridization.

The nuclear quadrupole interaction results from the non-spherical charge distribution over hybrid orbitals, the spherically symmetric closed-shell $s$ electrons contributing nothing. In accord with Fig. 4 showing the total electron distribution and Table V, a nearly cylindrically symmetric electron distribution in the valence shell of nitrogen and

FIG. 3. Variation of the nitrogen nuclear quadrupole coupling constant $\chi_{aa}(\text{N})$ of HONC along the minimum energy path in the direction of the bending angle $\beta$ involving hydrogen. Here, $\Delta \beta$ stands for the displacement $\beta - \beta_0$ from the equilibrium value $\beta_0$. The ground-state wave function probability amplitude $\Psi_0^2$ obtained from the corresponding one-dimensional calculation is additionally displayed.
largely asymmetric electron distribution in the valence shell of oxygen may readily be expected for HONC, resulting in an electric field gradient component $q_{uu}(^{14}\text{N})$ of 0.671 $E_h/a_0^2$ markedly smaller than $q_{uu}(^{17}\text{O})$ of 2.417 $E_h/a_0^2$. Since the magnitude of the nuclear quadrupole moment $Q(^{17}\text{O})$ of $-2.558$ fm$^2$ (Ref. 43) is comparable to $Q(^{14}\text{N})$, it follows $|\chi_{uu}(^{14}\text{N})|<|\chi_{uu}(^{17}\text{O})|$, as verified by our calculations reported elsewhere, where we find $\chi_{uu}(^{17}\text{O})$ of $-14.51$ MHz.

The highest occupied bonding molecular 9a’ orbital of HONC is compared with the highest occupied molecular 5σ+ orbital of HNC in Fig. 5. The molecular 9a’ orbital of HONC at $-0.491$ $E_h$ lies 0.023 $E_h$ below the highest occupied nonbonding out-of-plane 2a” orbital at $-0.468$ $E_h$ shown in Fig. 1. The molecular orbitals of Fig. 5 are very similar, both clearly exhibiting a promotion of $p_z$ electrons from nitrogen toward carbon and an electron cloud on carbon. In consequence, HONC and HNC possess similar equilibrium $r_{\text{CN}}$ bond lengths [1.173 Å versus 1.169 Å (Ref. 34)] due to a similar type of binding, schematically described as $\text{N}^+\text{C}^-$. Figure 5, as well as Figs. 1 and 4, were drawn with the help of the pre- and postprocessing program MOLDEN.

III. LABORATORY MEASUREMENTS AND RESULTS

The rotational spectrum of HONC was detected with the same Fourier transform microwave spectrometer used to detect cyanic acid, HOCN, and many other reactive molecules of chemical and astronomical interest. Many of these are radicals and carbenes, but positively and negatively charged species have been studied as well. Reactive molecules are created in the throat of a small supersonic nozzle by applying a low-current dc discharge to a short gas pulse created by a fast mechanical valve.

Like fulminic and cyanic acid, isofulminic acid is a closed-shell asymmetric rotor near the protonate limit ($\kappa = -0.9994$), with a nearly linear heavy-atom backbone closely parallel to the $a$ inertial axis (see Fig. 2), and a large rotational constant $A$ (see Table I). Both intrastack $a$-type ($\Delta K_a=0$) and interstack $b$-type ($\Delta K_a=\Delta K_b = \pm 1$) rotational transitions are allowed, and the calculated dipole moments along the two principal axes are fairly large ($\mu_a = 3.13$ D, $\mu_b = -1.54$ D; see Fig. 2). At the very low rotational temperature of our molecular beam ($T_{\text{rot}} \sim 3$ K), however, only levels in the $K_a=0$ ladder will be thermally populated, and the rotational spectrum of HONC simplifies to that of a linear molecule, with lines separated in frequency by approximately $B+C \sim 22$ GHz. Because of the relatively low frequency ceiling of our FTM spectrometer ($<42$ GHz), only the fundamental rotational transition ($1_{0,1} \rightarrow 0_{0,0}$) of HONC and its isomers is accessible with our present instrumentation. At the high spectral resolution (of order 0.1 ppm) which is readily achieved in our molecular beam experiments, however, the fundamental rotational line of HONC should possess a readily identifiable spectral fingerprint: a closely spaced, but well-resolved triplet with a characteristic 1:5:3 intensity ratio between the three lines, owing to nitrogen quadrupole hyperfine structure.

Our laboratory search for HONC was guided by rota-

IV. DISCUSSION

The present work firmly establishes the existence of the elusive isofulminic acid, and will permit a comparative study of all four isocyanic isomers. Although the data set is limited for HONC, with the isotopic data in hand, an experimental \(r_0\) structure for this bent chain can be derived assuming a nearly linear heavy-atom ONC backbone \(\angle(\text{ONC}) = 172.6^\circ\) and \(\angle(\text{HON}) = 105^\circ\). On this basis we derive bond lengths of \(r_{CN}^0 = 1.177(3)\ \text{Å}\), \(r_{NO}^0 = 1.333(3)\ \text{Å}\), and \(r_{OH}^0 = 0.958(3)\ \text{Å}\). Making use of the ground-state vibrational corrections \(\Delta R_c^{\text{(v)}}\) and \(\Delta R_e^{\text{(v)}}\) from Table I in combination with the experimental results \(B_{\text{eff}}\) we obtain experimental equilibrium bond lengths given by \(r_{CN}^e = 1.1744(4)\ \text{Å}\), \(r_{NO}^e = 1.3304(4)\ \text{Å}\), and \(r_{OH}^e = 0.9605(4)\ \text{Å}\). The latter results are in good agreement (to better than \(±0.005\ \text{Å}\)) with those predicted from theory, Fig. 2, providing thus a further evidence that the real “carboxime”\(^{51}\) with the structure HO–N=\(\equiv\)C has indeed been found. Analytical expressions for the principal moments of inertia in the bond-distance-bond-angle description and for their partial derivatives with respect to the geometrical parameters were employed here in combination with a Levenberg–Marquardt nonlinear least-squares algorithm\(^{52}\) to compute the experimental equilibrium bond lengths \(r_{CN}^e\), \(r_{NO}^e\), and \(r_{OH}^e\).

It is rather remarkable that isofulminic acid, calculated to lie 84 kcal/mol or nearly 4 eV above isocyanic acid, is readily produced in electric discharges starting from a wide variety of precursor gases containing H, C, N, and O. We estimate from line intensities that abundances relative to HNCO are 12% for HOCN, 2% for HCNO, and 1% for HONC in the molecular beam. Now that all four isocyanic isomers have been detected spectroscopically, it may be worthwhile to systematically measure relative abundances with different precursor combinations. Such a study might clarify the production routes that are operative in our discharge source.

Now that a simple but fairly efficient method for \(in\) situ synthesis of HONC has been demonstrated here, it should be possible to extend present work to the millimeter and sub-millimeter wavelengths to determine individual rotational and centrifugal distortion constants. Because HONC possesses a sizable dipole moment along the \(b\)-axis...
and a nearly comparable level of accuracy was recently achieved for another set of closed-shell molecules, the carbon-chain anions $C_n^+H^-$ ($n=1-4$), $53-55$ CN$^-56$ and $C_2N^-$. 57 Such close agreement suggests that the same theoretical methods might be applied to predict accurate spectroscopic constants for many other closed-shell molecules. It remains to be seen if 0.1% is the limit of present theory or not, and to critically assess if theoretical methods can be refined even further, perhaps by a factor of 10 or more, i.e., 0.01%. Even at the present level of accuracy, theoretical spectroscopic constants are an extremely helpful aid in the assignment of rotational spectra: they significantly reduce the frequency range of a laboratory search and well predict high-perfione structure.

Because HOCN and HCNO have recently been identified in space, detection of HONC is not out of the realm of possibility. It is calculated to lie only 14 kcal/mol higher in energy than HCNO and is comparably polar, so it may be found in warm regions where HCN is abundant. If detected in space, the abundance ratios between HONC and other isomers may provide further insight into the complex gas and surface chemistry, which is thought to produce these isomers. The discovery of HCNO in space, for example, led Marcelino et al. 15 to suggest that CH$_2$+NO→HCNO+H is a key reaction in the formation of fulminic acid, allowing them to reproduce the observed abundances of HCNO in both dark clouds and the low-mass star forming core L1527.
