ABSTRACT

This paper addresses the behaviour of a classical multi-antenna GLR test that allows to detect the presence of a known signal corrupted by a multipath propagation channel when the number of sensors $M$, the sample size $N$, and the number of paths $L$ are large and of the same order of magnitude. In the asymptotic regime where $M$, $N$ and $L$ converge towards $\infty$ at the same rate, the test statistics is shown to be asymptotically Gaussian under each hypothesis. The results of this paper extend previous contributions of the authors that addressed the case where the number of paths $L$ is much smaller than $M$ and $N$, and used these results in order to propose a pragmatic Gaussian approximation of the test statistics when $L$ is large. Simulation results indicate that the proposed Gaussian approximation of the test statistics is more reliable than the above mentioned pragmatic approximation.

Index Terms— Multichannel detection, asymptotic analysis, large random matrices

1. INTRODUCTION

Multivariate signals that are observed at the output of massive MIMO multi-antenna receivers are of course high-dimensional, and in this context, the available number of observations $N$ is very often of the same order of magnitude as the number of sensors $M$. It is now well understood that in this case, standard statistical multivariate signal processing problems such as source localization ([8], [11]), source power estimation ([4]), detection ([7],[9], [2]), or synchronization ([10]) need to be revisited, since standard statistical methodologies provide reliable results only when the ratio $\frac{M}{N}$ is small enough.

In [10], we addressed the detection problem of a known synchronization sequence transmitted by a single transmitter in an unknown multipath propagation channel when the receiver is equipped with a massive antenna array. We assumed that the observations were corrupted by a temporally white, but spatially correlated (with un-
Y = (y_1, \ldots, y_N) can be written as

\[ Y = HS + V \]  

(1)

where \( V = (v_1, \ldots, v_N) \) is the additive noise matrix, \( H \) the \( M \times L \) channel matrix and \( S \) the \( L \times N \) matrix corresponding to the known synchronization sequence. In the following, we assume that \((v_n)_n \in \mathbb{Z}^j\) is an additive independent identically distributed complex Gaussian noise verifying

\[ E(v_n) = 0, \quad E(v_n v_n^*) = 0, \quad E(v_n v_n^*) = \sigma^2 R \]

where \( R > 0 \) satisfies \( \frac{1}{N} \text{Tr}(R) = 1 \). We also assume that the size \( N \) of the training sequence satisfies \( N > M + L \). In this paper, we study the classical problem of testing the hypothesis \( H_1 \) characterized by Eq. (1) against the hypothesis \( H_0 \) defined by

\[ Y = V \]  

(2)

We assume from now on that \( H, \sigma^2 \) and \( R \) are unknown at the receiver side. In this context, it is well established (see e.g. [3]) that the generalised maximum likelihood test consists in comparing the following statistics \( \eta_N \) to a threshold:

\[ \eta_N = -\log \det [I_L - T_N] \]  

(3)

where \( T_N \) is the \( L \times L \) matrix defined by

\[ T_N = \left( \frac{SS^*}{N} \right)^{-1/2} \left( \frac{SY^*}{N} \right) \left( \frac{YV^*}{N} \right) \left( \frac{SS^*}{N} \right)^{-1/2} \]  

(4)

In order to study the behaviour of the test above, we study the limit distribution of \( \eta_N \) under each hypothesis. For this, we recall that it is possible to assume without restriction that the matrix \( S \) verifies \( SS^* = I_L \) and that \( \mathbb{E}(v_n v_n^*) = \sigma^2 I \), i.e. the matrix \( R \) is reduced to identity. Moreover, there exist two independent \( M \times (N-L) \) and \( M \times L \) complex Gaussian matrices \( V_1 \) and \( V_2 \) with i.i.d. \( \mathcal{N}_C(0, \sigma^2) \) entries such that \( \eta_N \) can be written as

\[ \eta_N = \log \det \left( I_L + \frac{V_1 V_1^*}{\sqrt N} \right) \]  

(5)

under hypothesis \( H_0 \), and as

\[ \eta_N = \log \det (I_N + G_N) \]  

(6)

under hypothesis \( H_1 \). Here, the matrix \( G_N \) is defined by

\[ G_N = \left( H + \frac{V_2}{\sqrt N} \right) \left( \frac{V_1 V_1^*}{N} \right)^{-1} \left( H + \frac{V_2}{\sqrt N} \right) \]  

(7)

For more details, we refer the reader to section II of [10]. In the following sections, we study the asymptotic behaviour of the distribution of \( \eta_N \) in the following asymptotic regime:

**Assumption 1.** \( M, N, L \) converge towards \( +\infty \) in such a way that \( c_N = \frac{M}{N} \) and \( d_N = \frac{L}{N} \) converge towards \( c > 0 \) and \( d > 0 \) with \( c + d < 1 \).

In order to simplify the notations, this regime will be denoted as \( N \to +\infty \). We note that the condition \( c + d < 1 \) is consistent with the assumption that \( M + L < N \). As the dimensions of the matrix \( H \) grow with \( M, N, L \), we also have to specify the behavior of \( H \). In the following, we assume that \( \sup_N \|H\| < +\infty \), i.e. that the spectral norm of \( H \) remains finite when its dimensions increase. We finally recall that the behaviour of \( \eta_N \) under hypothesis \( H_0 \) follows from existing mathematical results (see below for more details), and therefore concentrate on the behaviour of \( \eta_N \) under hypothesis \( H_1 \).

**3. Review of the Results of [10].**

In this section, we review the main results of [10], concentrating on the pragmatic approximation of \( \eta_N \) under Assumption 1 and hypothesis \( H_1 \). In order to explain the structure of this pragmatic approximation, we first recall the behaviour of \( \eta_N \) when the number of paths \( L \) remains fixed. The following result holds.

**Theorem 1.** In the asymptotic regime where \( M, N \) converge towards \( +\infty \) in such a way that \( c_N = \frac{M}{N} \) converges towards \( c < 1 \) and where \( L \) is a fixed parameter that does not scale with \( M, N \), under hypothesis \( H_1 \), it holds that

\[ (\delta_{N,1})^{-1/2} (\eta_N - \overline{\eta}_{N,1}) \to \mathcal{N}_B(0, 1) \]  

(8)

where \( \overline{\eta}_{N,1} \) and \( \delta_{N,1} \) are defined by

\[ \overline{\eta}_{N,1} = L \frac{c_N}{1 - c_N} + \log \det (I + H^* H / \sigma^2) \]

\[ \delta_{N,1} = \frac{L}{N} \frac{c_N}{1 - c_N} + \frac{\kappa}{N} \]

with \( \kappa = \text{Tr} \left( I - (I + H^* H / \sigma^2)^{-2} \right) \).

**Remark 1.** As \( L \) remains finite, the dimensions of the \( L \times L \) matrix \( G_N \) defined by (7) do not grow when \( M, N \to +\infty \). Therefore, in order to study the behaviour of \( \eta_N = \log \det (I_L + G_N) \), it is sufficient to evaluate the behaviour of each entry of \( G_N \) and to use a classical linearization argument. We also remark that the asymptotic variance of \( \eta_N \) converges towards 0 at rate \( \frac{1}{N} \).

**Remark 2.** The results related to hypothesis \( H_0 \) are obtained from the results concerning \( H_1 \) by setting \( H = 0 \).

We now recall the behaviour of the distribution of \( \eta_N \) under hypothesis \( H_0 \) in the regime defined by Assumption 1.

**Proposition 1.** In the asymptotic regime defined by Assumption 1, under \( H_0 \), it holds that

\[ (\delta_{N,2})^{-1/2} (\eta_N - \overline{\eta}_{N,2}) \to \mathcal{N}_B(0, 1) \]  

(9)

where \( \overline{\eta}_{N,2} \) and \( \delta_{N,2} \) are defined by

\[ \overline{\eta}_{N,2} = -N (1 - c_N) \log (1 - c_N) + (1 - d_N) \log (1 - d_N) \]

\[ + N (1 - c_N - d_N) \log (1 - c_N - d_N) \]

\[ \delta_{N,2} = \log \left( \frac{(1 - c_N)(1 - d_N)}{1 - c_N - d_N} \right) \]  

(10)

**Remark 3.** We remark that in contrast with the case where \( L \) remains fixed, it is not sufficient to evaluate the behaviour of the individual entries of matrix \( G_N \) in order to obtain the behaviour of \( \eta_N \). (9) follows from the observation that

\[ \eta_N = \log \det \left( I_M + \frac{V_2 V_2^*}{N} \right) \left( \frac{V_1 V_1^*}{N} \right)^{-1} \]

and thus coincides with a linear statistics of the eigenvalues of the matrix \( V_2 V_2^* / N (V_1 V_1^* / N)^{-1} \). This matrix is a Fisher matrix, and the asymptotic behaviour of \( \eta_N \) follows from the results of [1] and [12].
Remark 4. We mention that $\pi_{N,2}$ increases linearly with $M, N, L$, and that the asymptotic variance $\delta_{N,2}$ is a $O(1)$ term. This in contrast with the regime $L$ fixed in which the asymptotic mean is a $O(1)$ term and the asymptotic variance is a $O(1/N)$ term. We finally mention that it can be shown that the relative error between $\mathbb{E}(\eta_N)$ and its approximation $\pi_{N,2}$ is $O(1/N^2)$ for each $\epsilon > 0$.

As mentioned in [10], the asymptotic mean and the asymptotic variance of $\eta_N$ in the regime $M, N$ converge towards $+\infty$ and $L$ remains finite have an additive structure: $\pi_{N,1}$ is the sum of two terms: the asymptotic mean of $\eta_N$ under $H_0$ in the considered asymptotic regime (i.e. $L \log_2(1 + \frac{e}{N})$) and the asymptotic mean of $\eta_N$ in the standard asymptotic regime where $N \to +\infty$ and $L, M$ are fixed (i.e. $\log_2((1 + \frac{e}{N})$). The asymptotic variance is also the sum of the asymptotic variance under $H_0$ (i.e. $\frac{L}{N} (\frac{e}{N})$) with the asymptotic variance under $H_1$ in the regime $N \to +\infty$ and $M, L$ fixed (i.e. $\frac{c}{N}$). Proposition 1 as well as the additive structure of $\pi_{N,2}$ and $\delta_{N,2}$ suggested us to propose in [10] to approximate the distribution of $\eta_N$ under $H_1$ in regime defined by Assumption 1 by a $N \pi_{N,3}(\pi_{N,3}, \delta_{N,3})$ where $\pi_{N,3} = \pi_{N,2} + \log_2((1 + H^*H/\sigma^2))$ (i.e. the sum of the asymptotic mean of $\eta_N$ under $H_0$ with the asymptotic mean of $\eta_N$ when $N \to +\infty$ and $M, L$ remain fixed) and $\delta_{N,3} = \delta_{N,2} + \frac{c}{N}$ (i.e. the sum of the asymptotic variance of $\eta_N$ under $H_0$ with the asymptotic variance of $\eta_N$ when $N \to +\infty$ and $M, L$ remain fixed). The numerical results of [10] showed that the approximation $N \pi_{N,3}(\pi_{N,3}, \delta_{N,3})$ is more accurate than the approximation $N \pi_{N,2}(\pi_{N,2}, \delta_{N,1})$ even if $L$ remains small compared to $M, N$.

4. GAUSSIAN APPROXIMATION OF $\eta_N$ UNDER HYPOTHESIS $H_1$.

In this section, we present the main result of this paper, and point out the connections between the proposed Gaussian approximation of $\eta_N$ and the pragmatic approximation $N \pi_{N,3}(\pi_{N,3}, \delta_{N,3})$ proposed in [10]. In order to introduce our theorem, we have to introduce some notations. We first define $s_N$ as the unique positive solution of the equation

$$s_N = \frac{1}{M} \text{Tr} \left( \sigma^2 (1 - c_N) I + \frac{HH^*}{1 + \sigma^2 c_N s_N} \right)^{-1}$$

and denote by $S_N$ the $M \times M$ matrix given by

$$S_N = \left( \sigma^2 (1 - c_N) I + \frac{HH^*}{1 + \sigma^2 c_N s_N} \right)^{-1}$$

The following result holds.

Theorem 2. Under Assumption 1 and hypothesis $H_1$, it holds that

$$(\delta_N)^{-1/2}(\eta_N - \pi_N) \to_D N \pi_{N}(0, 1) \tag{13}$$

where $\pi_N$ and $\delta_N$ are defined by

$$\pi_N = \log_2 \left( \left( 1 - c_N \right) I + \frac{HH^*}{\sigma^2 (1 + \sigma^2 c_N s_N)} \right) +$$

$$M \sigma^2 (1 - c_N) \left( \frac{1}{\sigma^2 (1 - c_N)} - s_N \right) + N \log (1 + \sigma^2 c_N s_N) -$$

$$N ((1 - d_N) \log (1 - d_N) - (1 - c_N - d_N) \log (1 - c_N - d_N)) \tag{14}$$

and

$$\delta_N = \log \left( \frac{1 - d_N}{1 - c_N - d_N} \right) - \log \left( 1 + \sigma^2 c_N (1 - c_N) \right) \frac{1}{M} \text{Tr}(S_N^2) \tag{15}$$

The proof of this result is quite intricate, and we will only provide the general strategy. We first mention that using existing results concerning the so-called Information + Noise models (see e.g. [6], [5]), it is easy to establish that $E(\eta_N) = \tilde{\pi}_N + O(\frac{1}{N^2})$ for each $\epsilon > 0$. The difficult part of the proof consists in evaluating the asymptotic behaviour of the characteristic function $g_N(u)$ of $\eta_N - E(\eta_N)$. The general approach we follow is based on the following expression of $g_N(u)$:

$$g_N(u) = \mathbb{E} \left[ e^{iu(\mathbb{E}(V_1|\eta_N) - \mathbb{E}(\eta_N))} \right] \mathbb{E} \left[ e^{iu(\eta_N - \mathbb{E}(V_1|\eta_N))} | V_2 \right]$$

where $\mathbb{E}(V_1)$ represents the mathematical expectation operator w.r.t. $V_1$ and where $\mathbb{E}(., | V_2)$ is the conditional expectation operator given $V_2$. It is possible to establish that for each $u$,

$$\mathbb{E} \left( e^{iu(\eta_N - \mathbb{E}(V_1|\eta_N))} | V_2 \right) \approx e^{-\xi_N u^2/2}$$

where $\xi_N$ represents a positive deterministic term. From this, we deduce that

$$g_N(u) \approx e^{-\xi_N u^2/2} \mathbb{E} \left[ e^{iu(\eta_N - \mathbb{E}(V_1|\eta_N))} \right]$$

and prove that $\mathbb{E} \left[ e^{iu(\eta_N - \mathbb{E}(V_1|\eta_N))} \right] \approx e^{-\xi_N u^2/2}$. This, in turn, implies that $g_N(u) \approx e^{-(\xi_N + \xi_N^2) u^2/2}$ and that $(\xi_N + \xi_N) u^{-1/2} (\eta_N - E(\eta_N))$ converges in distribution towards a $N(0, 1)$ random variable. We finally comment on Theorem 2.

We first mention that if $H = 0$, then, $s_N$ defined by Eq. (11) coincides with $\frac{1}{\sigma^2 (1 - c_N)}$, and that $\tilde{\pi}_N$ and $\delta_N$ coincide with $\pi_{N,2}$ and $\delta_{N,2}$ respectively.

We now compare the pragmatic approximation $N \pi_{N}(\pi_{N,3}, \delta_{N,3})$ with the approximation provided by Theorem 2 in the case where $\text{Tr}(HH^*)$ remains bounded when $N \to +\infty$. In this case, it is easy to check that $s_N$ defined by Eq. (11) can be written as

$$s_N = \frac{1}{\sigma^2 (1 - c_N)} + O\left( \frac{1}{N} \right)$$

Using standard first order expansions, we obtain immediately that $\pi_{N,3} = \pi_{N} + O\left( \frac{1}{N} \right)$ and $\delta_{N,3} = \delta_{N} + O\left( \frac{1}{N} \right)$. Therefore, when $\text{Tr}(HH^*)$ remains bounded, the two approximations tend to coincide. We remark that the signal to noise ratio at the receiver side coincides with $\frac{\text{Tr}(HH^*)}{\text{Tr}(G^*G)}$, so assuming that $\text{Tr}(HH^*)$ remains bounded implies in practice that the signal to noise ratio is low. This condition is of course much stronger than the condition that $|H|$ remains bounded, which, rather, implies that $\text{Tr}(HH^*) = O(M)$, and corresponds to high signal to noise ratios. Therefore, at moderate signal to noise ratios, the pragmatic approximation $N \pi_{N}(\pi_{N,3}, \delta_{N,3})$ behaves as the rigorous one, thus explaining the accuracy of the pragmatic Gaussian approximation of [10].

5. NUMERICAL RESULTS

In this section, we compare the accuracies of the approximations $N \pi_{N}(\pi_{N,3}, \delta_{N,3})$ and $N \pi_{N}(\pi_{N}, \delta_{N})$. The true mathematical expectation and the true variance of $\eta_N$, as well as the ROC curves corresponding to the GLRT, are evaluated by generating $10^5$ independent realizations of $\eta_N$. In each experiment, the matrix $H$ is generated as $H = G / (\text{Tr}(GG^*))^{1/2}$ where $G$ is a realization of a $M \times L$ random matrix with i.d. $N(0, 1)$ entries. Therefore, $H$ is normalized in such a way that $\text{Tr}(HH^*) = 1$, and the signal to noise ratio
coincides with $\frac{1}{2}$. Finally, in all our experiments, $c_N = M/N$ is fixed to $1/2$, while $d_N = L/N = 1/4$.

We first represent for various values of $L$ in figures 1 and 2 the relative errors on $E(\eta N)$ and on $\text{Var}(\eta N)$ provided by the two approximations when $\frac{\sigma^2}{N} = \frac{M}{24}$ (low SNR) and $\frac{\sigma^2}{N} = \frac{M}{7}$ (high SNR). We recall that for each value of $L, M$ and $N$ satisfy $d_N = 1/4$ and $c_N = 1/2$. As expected, the proposed approximation $N_R(\eta N, \delta_N)$ appears much more accurate than $N_R(\eta N, \delta_N, 3)$, and the accuracy of the latter tends to decrease when the SNR increases. In other words, for low SNR, both approximations are valid (although the proposed approximation gives a more accurate theoretical expected value), but with high SNR, $N_R(\eta N, \delta_N, 3)$ is less accurate.

In order to validate the asymptotic Gaussianity of $\eta N$ under $H_1$, we show in figure 3 the histogram of the realizations of $\eta N$, together with the probability densities of $N_R(\eta N, \delta_N, 3)$ and $N_R(\eta N, \delta_N)$. In figure 3, $L = 20$ and $\frac{\sigma^2}{N} = M/7$ (high SNR). It is clear that the proposed asymptotic distribution offers a better fit with the empirical distribution of $\eta N$.

We finally evaluate the accuracy of the two approximations by comparing their theoretical ROC curves to the empirical ROC curve evaluated from the $10^7$ realizations of $\eta N$. For each approximation, the threshold corresponding to each false alarm probability is evaluated using the Gaussian approximation $N_R(\eta N, \delta_N, 3)$ of $\eta N$ under $H_0$. Figures 4 and 5 represent the three ROC curves for two different SNR values and $L = 20$ and $L = 50$ respectively. The ROC curve corresponding to the proposed approximation appears more accurate than the ROC curve associated to $N_R(\eta N, \delta_N, 3)$

6. CONCLUSION

In this paper, we have established a central limit theorem for the GLRT statistics $\eta N$ under hypothesis $H_1$ in the asymptotic regime where the dimensions $N, M, L$ all go to infinity at the same rate. The corresponding asymptotic expected value and variance are expressed in closed form. It is established that the pragmatic Gaussian approximation proposed in [10] tends to have the same accuracy than the new approximation at low SNR, but that the performance of the new proposal is much better at high SNR. Simulation results confirm these theoretical claims, and demonstrate that the proposed Gaussian approximation allows to predict in a reliable way the ROC curves of the GLRT.
